

Predicting N₂O emissions from nitrifying and denitrifying biofilms: a modeling study

Fabrizio Sabba, Cristian Picioreanu, Joshua P. Boltz and Robert Nerenberg

ABSTRACT

Wastewater treatment plants can be significant sources of nitrous oxide (N₂O), a potent greenhouse gas. While our understanding of N₂O emissions from suspended-growth processes has advanced significantly, less is known about emissions from biofilm processes. Biofilms may behave differently due to their substrate gradients and microbial stratification. In this study, we used mathematical modeling to explore the mechanisms of N₂O emissions from nitrifying and denitrifying biofilms. Our ammonia-oxidizing bacteria biofilm model suggests that N₂O emissions from biofilm can be significantly greater than from suspended-growth systems. The driving factor is the diffusion of hydroxylamine, a nitrification intermediate, from the aerobic to the anoxic regions of the biofilm. The presence of nitrite-oxidizing bacteria further increased emissions. For denitrifying biofilms, our results suggest that emissions are generally greater than for suspended-growth systems. However, the magnitude of the difference depends on the bulk dissolved oxygen, chemical oxygen demand, and nitrate concentrations, as well as the biofilm thickness. Overall, the accumulation and diffusion of key intermediates, i.e. hydroxylamine and nitrite, distinguish biofilms from suspended-growth systems. Our research suggests that the mechanisms of N₂O emissions from biofilms are much more complex than suspended-growth systems, and that emissions may be higher in many cases.

INTRODUCTION

Nitrous oxide (N₂O) is a potent greenhouse gas, with a global warming potential 300 times greater than that of CO₂ (IPCC 2013). Wastewater treatment plants can be an important source of N₂O (Ahn *et al.* 2010). Emissions from wastewater may result from incomplete denitrification (Kampschreur *et al.* 2009; Lu & Chandran 2010; Pan *et al.* 2012), but also from nitrification (Tallec *et al.* 2006; Kampschreur 2008; Kampschreur *et al.* 2009; Lu & Chandran 2010; Wunderlin *et al.* 2012; Ye *et al.* 2014; Daelman *et al.* 2015). During nitrification, N₂O emissions may result from nitrifier denitrification as well as chemical degradation of hydroxylamine (NH₂OH) (Schreiber *et al.* 2009, 2012; Harper *et al.* 2015; Soler-Jofra *et al.* 2016).

While extensive research has investigated N₂O formation in suspended-growth systems (Kimoichi *et al.* 1998; Colliver & Stephenson 2000; Kampschreur *et al.* 2008; Ahn *et al.* 2010; Lu *et al.* 2010; Aboobakar *et al.* 2013), few studies have explored its formation in biofilm-based processes, such as the moving bed biofilm reactor, biological

aerated filter, and granular sludge. Such processes have been gaining in popularity, and therefore it is important to understand their potential for N₂O emissions.

Bacteria in suspended-growth systems are directly exposed to the bulk liquid. Thus, the formation of N₂O depends exclusively on the conditions in the bulk environment. For example, little or no N₂O formation would be expected from denitrifying bacteria if the bulk is fully aerobic, as denitrification would be inhibited by O₂. In a biofilm, however, O₂ gradients exist. Even if the bulk liquid were aerobic, bacteria in the deeper biofilm could experience anoxic conditions, allowing nitrate reduction and the formation of N₂O.

A number of models have been developed to predict N₂O formation by nitrifying (Kampschreur *et al.* 2007, 2008; Ni *et al.* 2011; Mampaey *et al.* 2013; Ni *et al.* 2013, 2014) and denitrifying microorganisms (Hiatt & Grady 2008; Ni *et al.* 2011; Kampschreur *et al.* 2012; Pan *et al.* 2013). In particular, recent models have improved the prediction of N₂O by

explicitly considering formation and consumption of nitrification and denitrification intermediates, and modeling the competition of key enzymes for intracellular electron mediators (Pan *et al.* 2013; Ni *et al.* 2014; Ni & Yuan 2015). A recent study used such a model to predict the mechanisms of N₂O formation from nitrifying biofilms containing ammonia-oxidizing bacteria (AOB) (Sabba *et al.* 2015). However, this study did not consider the effects of nitrite-oxidizing bacteria (NOB) in nitrifying biofilms, nor did it assess the effects of gas stripping, e.g. via aeration. More importantly, there are no studies addressing the mechanisms of N₂O formation from denitrifying biofilms.

The objective of this study was to use mathematical modeling to systematically explore N₂O production and emissions from nitrifying and denitrifying biofilms. Note that we use the words N₂O *production* (the net formation of N₂O from the biofilm) and *emissions* (loss of N₂O from the reactor in liquid and gas phases) interchangeably in this paper. Also, the intent was not to accurately predict N₂O emissions, but to explain how the mechanisms of N₂O formation in biofilm differ from those from in suspended growth systems. We assessed N₂O emissions from nitrifying biofilms consisting solely of AOB, or AOB plus NOB. Denitrifying biofilms were studied separately, to clearly establish the mechanisms of N₂O formation by each population.

METHODS

The biofilm models used to predict N₂O production in biofilms were based on traditional diffusion-reaction mass balances for the relevant chemical species in both nitrifying and denitrifying biofilms.

The nitrifying model considered N₂O formation by AOB via two pathways: the hydroxylamine (NH₂OH) pathway and the nitrifier denitrification pathways. This approach is based on a recently published model (Ni *et al.* 2014; Sabba *et al.* 2015). While in our previous work we focused on the mechanisms of N₂O formation in biofilms consisting exclusively of AOB (Sabba *et al.* 2015), in this work we expanded on the previous work and explored the effects of gas stripping and of the combined presence of AOB and NOB within the biofilm. Furthermore, we studied the mechanisms of N₂O emissions in denitrifying biofilms, with and without gas stripping.

Parameters for the nitrification model are reported in Table 1. While a base AOB density, assuming uniform distribution of AOB, was used in most studies, different biomass densities were also tested. For additional tests with AOB

along with a constant and uniformly distributed population of NOB, the NOB were simulated using the conventional ASM model, i.e. without electron mediators (Piciooreanu *et al.* 1997). The denitrifying model included N₂O formation by heterotrophic bacteria, and was adapted from Pan *et al.* (2013).

A continuous, ideally-mixed biofilm reactor incorporating nitrifying or heterotrophic bacteria was modeled. The two separate models evaluated 1-dimensional, planar biofilms. A hydraulic retention time of 6 hours for the nitrifying and 1.5 hours for the denitrifying condition was used. As initial values, all concentrations in biofilm and bulk liquid were taken equal to the corresponding influent concentrations. As base condition, a biofilm specific surface area of 125 m² m⁻³ was used. Biomass growth, decay, attachment and detachment were not considered. Biofilms of different thicknesses were modeled. Thicknesses of 2 μm for the nitrifying and 5 μm for the denitrifying biofilm were assumed to represent 'suspended growth'. While these thicknesses were chosen arbitrarily, they both had essentially had no substrate gradients within the depth and therefore behaved as suspended growth.

For the denitrification process, O₂, nitrite (NO₂⁻), nitric oxide (NO), N₂O, nitrate (NO₃⁻) and chemical oxygen demand (COD) were included as state variables. Note that the COD is assumed to be readily biodegradable. For the nitrification process, the model additionally considered ammonia (NH₃) and NH₂OH as state variables, but did not include COD. The conditions tested in both models are listed in Tables 1 and 2. All model equations and process matrices are provided in the Supporting Information in Tables S1–S3 for the nitrifying model and Table S4–S6 for the denitrifying model. The denitrification model was used to predict the effects of bulk O₂ and NO₃⁻ concentrations on N₂O production in denitrifying biofilms, assuming an influent NO₃⁻ concentration of 14 mgN L⁻¹. The bulk COD concentration was 720 mgCOD L⁻¹, such that COD was not rate limiting within the biofilm. The assessed biofilm thicknesses were 5, 50 and 400 μm. In the denitrification model, we added an O₂ reduction process with a high maximum reduction rate, q_{max}, and a very high relative affinity for M_{red} such that O₂ reduction was prioritized over denitrification. This novel approach to modeling O₂ inhibition guarantees that, as long as O₂ is present, it will keep M_{red} at very low levels and inhibit the reduction of nitrogen oxides. This approach is a more fundamental alternative to the conventional 'oxygen switch' used in the ASM models, and allows the distinct inhibitory effect of O₂ on each enzyme to be included via the M_{red} concentration.

Most modeling runs were without N₂O stripping. However, for some runs we explored the effects of stripping on N₂O emissions. As NO usually does not accumulate and

acts as a transient compound, its stripping was not included in the model. To simulate N₂O stripping during aeration, an additional transfer term was included in the liquid N₂O mass balance as $k_L a (C_{G,N_2O} H_{N_2O} - C_{B,N_2O})$, and a further equation was solved for the gas phase concentration, C_{G,N_2O} (mol/m³ gas), as $dC_{G,N_2O}/dt = Q_G/V_G(0 - C_{G,N_2O}) - k_L a (C_{G,N_2O} H_{N_2O} - C_{B,N_2O})$.

The model was implemented on the COMSOL Multiphysics platform. Equations for one-dimensional diffusion and reaction, for a fixed biofilm density and thickness, were solved with variable time step on a biofilm domain discretized with a mesh size of 1 μm. Steady state was assumed to be reached when effluent concentrations were stable. Steady state for all conditions was obtained after maximum simulation time of three days for nitrifying biofilms and one day for heterotrophic biofilms.

A summary of the nitrifying and denitrifying conditions used for the model can be found in Tables 1 and 2, respectively. A complete list of stoichiometric matrices, reaction rates and other model parameters for both models can be found in the Supporting Info (Tables S1–S6).

RESULTS AND DISCUSSION

Nitrifying biofilms

Effect of O₂ and thickness on N₂O emissions

We first explored N₂O emissions from an AOB biofilm as a function of bulk O₂ for biofilm thicknesses of 2, 50, and 100 μm. We then selected one biofilm thickness, 100 μm,

and analyzed its behavior in more detail. Finally we evaluated the effects of NOB on the overall N₂O emissions.

The nitrifying model suggests that thicker biofilms have greater N₂O emissions than thin biofilms, which represent suspended-growth systems (Figure 1(a)). A range of thicknesses was simulated. The emission rates increased with increasing in O₂. However, this behavior was different for thinner biofilms and suspended growth systems, where N₂O reached its maximum at much lower O₂ levels than for thicker biofilms. Biofilms with greater thicknesses (e.g. 50 and 100 μm) followed similar general trends with regards to N₂O emissions (Figure 1(a)). This trend confirmed that thicker biofilms not only had higher emissions, but also had N₂O emissions for a much wider range of O₂ values. The main cause is the diffusion of NH₂OH, an AOB nitrification intermediate. Diffusion of reaction intermediates has been previously shown (De Beer *et al.* 1998; Stewart 2003; Sabba *et al.* 2015). NH₂OH forms in the outer, aerobic regions of biofilm and diffuses to the inner, anoxic regions of the biofilm (Figure 1(b)). The higher emissions for thicker biofilms occurred on a basis of a higher biomass content for biofilms, respectively.

To better understand and explore mechanisms that lead to N₂O formation, a base case of a 100-μm biofilm was considered (Figure 1(b)). Figure 1(b) shows the net rates of formation or consumption of nitrifying key species and O₂. In a suspended-growth system at steady state, the rate of NH₃ oxidation should equal the rate of NH₂OH oxidation. In biofilms, however, some NH₂OH may diffuse into the deeper portions of the biofilm, resulting in a net formation of NH₂OH in the outer biofilm and net consumption in the interior (Figure 1(b)).

Figure 1 | (a) N₂O production rates for AOB biofilms of different thicknesses with a constant biofilm surface area, per unit reactor volume, as a function of bulk O₂, and (b) net component rates over the biofilm depth (x) for the 100-μm biofilm. Results are for the base case conditions at a bulk O₂ of 0.9 mg L⁻¹.

The external portion of the biofilm (right side of Figure 1(b)) has high nitrification rates due to the high concentrations of NH₃ and O₂. This can be seen in Figure 1(b), where there is net consumption of both compounds and net formation of NH₂OH and NO₂⁻ as products. Essentially all of the electrons from NH₂OH oxidation are utilized for O₂ reduction in this zone, allowing little NO₂⁻ reduction. However, at greater depths, around 60 μm, O₂ becomes limiting and the rate of NH₃ consumption approaches zero. In this zone, little NH₃ reduction takes place, but electrons produced from NH₂OH that diffuses from the outer layers are used for NO₂⁻ reduction, leading to a spike in N₂O formation. Below 30 μm, NH₂OH is no longer available and the rate of N₂O formation decreases to zero. This is also true for larger thicknesses where different biomass concentrations might be present. With increasing thicknesses, the inner portions become inactive, while the amount of active biomass close to the bulk liquid remains similar. The NH₂OH pathway contributed only to a small extent to the N₂O overall production while the nitrifier denitrification pathway was the main contributor for most of the N₂O produced. These results are similar to those found by Sabba *et al.* (2015).

Effect of NOB on N₂O emissions

Sabba *et al.* (2015) studied a biofilm consisting solely of AOB. However, nitrifying biofilms commonly typically include both AOB and NOB. While NOB do not directly produce N₂O, they may affect N₂O formation by AOB by modifying the surrounding environment.

If the total density of AOB only is 50 g L⁻¹ (base case), and NOB provide an additional 15 g L⁻¹ density for a total of 65 g L⁻¹, the N₂O emissions increase with respect to the base case (Figure 2). This is because a higher overall biomass density of AOB and NOB leads to higher O₂ gradients in the biofilm. This promotes a higher gradient of NH₃ oxidation rates and O₂ concentrations, leading to greater diffusion of NH₂OH into the deeper biofilm. It also contributes to the formation of an anoxic zone within the biofilm depth.

Interestingly, even if the AOB density drops to 35 g L⁻¹, maintaining a total biofilm density of 50 g L⁻¹, the N₂O formation rates with NOB are higher than if the biofilm is exclusively composed of AOB. This is because NOB have a higher specific rate of oxygen consumption in our model. Based on these considerations, the presence of NOB in a nitrifying biofilm may actually increase N₂O emissions.

Figure 2 | Emissions from base case 100 μm nitrifying biofilm with AOB and NOB. The presence of nitrite oxidizers (NOB) in the biofilm may enhance the N₂O production. N₂O production rate without NOB (base case, AOB 50 g L⁻¹) and with 15 g L⁻¹ NOB (AOB 50 or 35 g L⁻¹).

Effects of gas stripping on N₂O emissions from nitrifying biofilms

In this section, we evaluated the effects of gas flow on both suspended growth (modeled as thin biofilms) and biofilm systems. Results are shown in Figure 3.

Note that our model did not include NO stripping due to aeration. NO stripping can reduce N₂O formation, as NO is a precursor to N₂O. However, our preliminary simulations show that NO is mostly converted to N₂O within the biofilm. NO stripping is more significant for thin biofilms, but these produce little NO due to the lack of substrate gradients.

Research has shown that N₂O can be stripped from suspended growth systems (Rassamee *et al.* 2011; Law *et al.* 2012; Wu *et al.* 2014). Including stripping simply shifts N₂O

Figure 3 | N₂O bulk liquid concentration for nitrifying conditions as a function of bulk O₂ for a 2 μm suspended growth and 100 μm biofilm system, with stripping (solid line) and without stripping (dashed line).

emissions from the liquid phase to the gas phase (Figure 3). When stripping was included, the N₂O concentration in the liquid phase, for both suspended and biofilm systems, decreased to near-zero levels (Figure 3). But this did not impact N₂O formation rates, since stripping was not linked to aeration and the O₂ concentration remained constant (data not shown). This situation is different for denitrifying bacteria (below), as stripping and biological reduction are competing processes, i.e. more stripping leads to less biological reduction in the biofilm.

Denitrifying biofilms

Effect of O₂ and NO₃⁻ on N₂O emissions

At low NO₃⁻ concentrations, emissions from the 5- μ m biofilm were higher than the thicker biofilms, but they quickly reached

a low maximum rate of N₂O production (Figure 4(a)). This is due to full penetration of NO₃⁻. The lower emissions at lower NO₃⁻ concentrations in the thicker biofilms are explained by the partial NO₃⁻ penetration within the biofilm depth. Thicker biofilms require higher NO₃⁻ concentrations to reach maximum denitrification rates throughout the biofilms. For greater biofilm thicknesses the higher biomass concentration accounted for higher rate of N₂O formation.

N₂O emissions from ‘suspended growth’ and biofilm systems were assessed for different O₂ bulk concentrations (Figure 4(b)). At low bulk O₂ concentrations the amount of N₂O produced per unit reactor volume for the 5- μ m ‘suspended growth’ scenario was higher than the thicker biofilms. Specifically, the 5- μ m scenario reached its maximum N₂O emissions at near-zero O₂ concentrations. The N₂O emissions then dropped steeply around 0.1 mg O₂ L⁻¹ and approached zero at around 0.3 mg O₂ L⁻¹. For the

Figure 4 | N₂O production rates for denitrifying biofilms of different thicknesses with a constant biofilm surface area, per unit reactor volume and time, as a function of bulk NO₃⁻ (a) and bulk O₂ (b). Net component rates over the biofilm depth (x). Results are for the base case conditions with anoxic bulk conditions (net rates of component formation or consumption) (c), and biofilm N-species concentration within biofilm depth (d). Results in (c) and (d) are for the base case conditions with a 400 μ m biofilm in presence of anoxic bulk.

400- μm biofilm, the emissions of N₂O were slightly higher at low bulk O₂ concentrations and then had minimal decrease with increasing O₂. This is due to the O₂ consumption of oxygen in the outer layers, allowing denitrification in the inner layers. In a similar fashion to Figure 4(a) greater biofilm thicknesses the higher volumetric biomass concentration accounted for higher rate of N₂O formation.

Finally, to better evaluate mechanisms of N₂O formation in denitrifying biofilms, a base biofilm thickness of 400 μm was considered in more detail (Figure 4(c)). For the 400- μm biofilm with an anoxic bulk, the bulk NO₂⁻ and N₂O concentrations were 0.12, and 0.07 mgN L⁻¹ (Figure 4(d)), respectively (data not shown). When both the NO₃⁻ concentration and the rate of NO₃⁻ reduction start to decrease, at around 300 μm , the NO₂⁻ reduction rate starts to increase and there is a net production of N₂O around 280 μm (data not shown). The inner portion of the biofilm, around 250 μm , has a low concentration of

NO₃⁻ and a higher net NO₂⁻ consumption rate (Figure 4(c)). In the last region of the biofilm, where NO₃⁻ is mainly depleted and NO₂⁻ is at low concentration, the N₂O consumption rate leads the process rates and uses the available electron mediators to reduce N₂O to N₂. Thus, this region is a net sink for N₂O produced in other regions of the biofilm or the bulk.

Effects of stripping on N₂O emissions

The effects of gas stripping were evaluated for a 5- μm system, representing suspended growth and a 400- μm biofilm system (Figure 5(a)–5(d)). Stripping may occur due to low levels of aeration or due to N₂ gas production. In Figure 5(a)–5(d), we compared N₂O production rates with and without stripping as a function of bulk NO₃⁻ for both suspended growth and biofilm systems. All these scenarios were tested for non-limiting COD conditions.

Figure 5 | N₂O production rates in denitrifying biofilms with a constant biofilm surface area, with and without stripping, for a 5- μm biofilm ('suspended growth') (a, c) and 400- μm biofilm (c, d) as a function of bulk NO₃⁻ (a, b) and (c, d) as a function of bulk O₂.

For the 5- μm 'suspended growth' biofilm, the maximum N₂O production rate was reached at very low NO₃⁻ concentrations (e.g. 0.1 mgN L⁻¹) (Figure 5(a)). This is because the thin biofilm becomes fully penetrated and saturated by NO₃⁻ at relatively low bulk concentrations. Stripping increases the N₂O emission by maintaining low bulk N₂O concentrations which allows the bulk liquid to become a sink for N₂O. Thicker biofilms require higher NO₃⁻ concentration to reach the maximum bulk N₂O concentration (Figure 5(b)). Stripping has a greater effect on thicker biofilms (Figure 5(b)).

The effects gas stripping on N₂O emissions as a function of bulk O₂ also were evaluated (Figure 5(c) and 5(d)). For suspended growth systems (5 μm biofilm) without stripping, no gaseous N₂O emissions occurred throughout the sweep of O₂ concentration for both biofilm and suspended growth. Higher emissions were found when stripping was included for both biofilm and suspended growth (Figure 5(c) and 5(d)). Emissions in this case represent the net emissions; comparing emissions by the formation rate in denitrifying systems would not allow a fair comparison since denitrifying systems might both produce and consume N₂O. For suspended growth systems, emissions were higher at low O₂. However, they dropped suddenly after the O₂ concentration reached 0.1 mg L⁻¹ where a full inhibition of the suspended growth occurred (Figure 5(c)). No emissions occurred afterwards. Biofilms performed differently (Figure 5(d)). They tended to have higher emissions throughout the O₂ sweep. Emissions were highest at low O₂, and decreased when O₂ increased.

CONCLUSIONS

Our model suggests that N₂O emissions from both nitrifying and denitrifying biofilms behave differently from suspended growth systems. In suspended growth systems, all bacteria are exposed to the same bulk concentrations of substrates and intermediates.

As found previously, NH₂OH formed in an aerobic zone of a nitrifying biofilm diffuses to an anoxic zone, resulting in a spike in N₂O formation rates and higher N₂O emissions. However a novel aspect of this study is that the presence of NOB also can enhance emissions. This was due to high rate of O₂ reduction by NOB, leading to an increase in the O₂ gradient within the biofilm.

Diffusion of intermediates was also important for the denitrifying biofilm, where NO₃⁻ and NO₂⁻ reduction govern the activity in the outer portion of the biofilm.

Thus, the inner portion of biofilm has lower concentrations of both compounds, and these can diffuse and be consumed elsewhere. This same aspect applies to N₂O, which can both be exported to the bulk and diffuse towards the deeper regions of a denitrifying biofilm and be reduced.

For denitrifying systems, gas stripping increased emissions by decreasing the amount of N₂O available for reduction in the deeper, anoxic regions of the biofilm. An increase in influent flow rate mimics stripping effects, creating a more pronounced gradient between biofilms and the bulk environment, leading to higher emissions.

These results identify important mechanisms that affect N₂O emissions in nitrifying and denitrifying biofilms. Future research should address behavior of biofilms containing both nitrifying and denitrifying bacteria, mimicking simultaneous nitrification and denitrification systems.
